Abstract In many social situations, we make a snap judgment about crowds of people relying on their overall mood (termed “crowd emotion”). Although reading crowd emotion is critical for interpersonal dynamics, the sociocultural aspects of this process have not been explored. The current study examined how culture modulates the processing of crowd emotion in Korean and American observers. Korean and American (non-East Asian) participants were briefly presented with two groups of faces that were individually varying in emotional expressions and asked to choose which group between the two they would rather avoid. We found that Korean participants were more accurate than American participants overall, in line with the framework on cultural viewpoints: Holistic versus analytic processing in East Asians versus Westerners. Moreover, we found a speed advantage for other-race crowds in both cultural groups. Finally, we found different hemispheric lateralization patterns: American participants were more accurate to perceive the facial crowd to be avoided when it was presented in the left visual field than the right visual field, indicating a right hemisphere advantage for processing crowd emotion of both European American and Korean facial crowds. However, Korean

participants showed weak or nonexistent laterality effects, with a slight right hemisphere advantage for European American facial crowds and no advantage in perceiving Korean facial crowds. Instead, Korean participants showed positive emotion bias for own-race faces. This work suggests that culture plays a role in modulating our crowd emotion perception of groups of faces and responses to them.

**Keywords** Culture · Crowd emotion · Ensemble coding · Face perception · Group perception

**Introduction**

We routinely encounter groups of people at work, school, or social gatherings. Efficiently reading the emotional states of crowds allows us to guide our own reactions and social behaviors. For example, rapidly inferring intent to commit violence from the facial expressions of a mob on the street can allow us to escape in time and avoid potential danger, perhaps by seeking help from another group that looks friendly. Likewise, reading the general mood and receptiveness of an audience allows us to adjust our ongoing behavior, by explaining in more detail or deferring on a point, for a more efficient communication. Such extraction of the prevailing crowd state can occur rapidly and efficiently, by representing the groups of faces as a higher-level description in the form of ensemble coding (Alvarez 2011; Cohen et al. 2016; Haberman and Whitney 2012). Ensemble coding is the perception of the sum of parts rather than the perception of the individual parts within the sum; the perception of the sum is based on summary statistics (e.g., mean and/or variance) computed from multiple measurements of the parts, either by collapsing across the individual parts or across space and/or time. The key idea here is that the visual system exploits redundancies and regularities in scenes to extract ensemble representations from groups of similar items, without having to examine each individual object. Recent work on ensemble coding has demonstrated human observers’ remarkable ability to extract average emotion (also termed “crowd emotion”) from sets of faces (e.g., Elias et al. 2016; Fischer and Whitney 2011; Haberman et al. 2009; Haberman and Whitney 2007; Hubert-Wallander and Boynton 2015; Im et al. 2017; Ji et al. 2014; Yang et al. 2013), facial identity (de Fockert and Wolfenstein 2009; Haberman and Whitney 2007; Leib et al. 2012, 2014; Neumann et al. 2013), as well as a crowd’s movements (Brunyé et al. 2014; Sweeney et al. 2012) and eye gaze direction (Florey et al. 2016; Sweeney and Whitney 2014).

Although perceiving average emotion of facial crowds is important in forecasting intentions of groups of people and governing observers’ reactions towards them (e.g., which group would be safe to approach or better to avoid; Im et al. 2017), little is known about sociocultural aspects of this process. To the best of our knowledge, only a single study has investigated the gender differences in recognizing average identity from a crowd of faces (Bai et al. 2015). It still remains unaddressed how different cultural groups (e.g., Westerners and Easterners) perceive crowd emotion when they see faces of same and different races (e.g., Caucasian and East Asian...
faces). The majority of previous studies on crowd emotion perception have exclusively employed photographs of Caucasian faces (Fischer and Whitney 2011; Haberman et al. 2009; Haberman and Whitney 2007; Hubert-Wallander and Boynton 2015; Im et al. 2017). Although all these studies have been conducted in the Western countries, the specific breakdown of the participants’ ethnic background was not available. We could find only a few exceptions that employed photographs of Asian faces (Chinese faces: Ji et al. 2014; Korean faces: Yang et al. 2013), but only when presented to a group of Chinese and Korean participants, respectively. Therefore, none of the existing studies on crowd emotion perception allows us to directly compare potential differences between Easterners and Westerners in extracting crowd emotion from groups of faces of Easterners. Please check and confirm that the affiliation I has been correctly identified and amend if necessary. Westerners. A within-subject design in which participants view both faces of crowds of Easterners and Westerners would be more effective than a between-subjects design because it would allow us to directly compare participants’ performance for facial crowds of different races and reduce potential error variance associated with individual differences across groups. Characterizing differences in the perception of own-race-crowds versus other-race-crowds between Western participants versus Eastern participants would represent an initial step in investigating the factors that mediate their different perceptual styles.

There is growing interest in empirically testing how differences in cultural experiences shape the way we perceive and respond to the visual world (for reviews, Han et al. 2012; Koelkebeck et al. 2017). Studies comparing Westerners and Easterners have provided convergent evidence for the different perceptual and cognitive styles of those populations (e.g., Lao et al. 2013; Nisbett and Miyamoto 2005; Nisbett et al. 2001). For example, Westerners preferably focus on local information, whereas Easterners tend to show perceptual biases towards global information processing in objects (e.g., Masuda and Nisbett 2001), scene (e.g., Masuda and Nisbett 2008), and face perception (e.g., Blais et al. 2008; Caldara et al. 2010). Recent evidence also suggests that such cultural differences might rely on different tuning towards visual spatial frequency information across cultural groups (e.g., Miellet et al. 2013). For example, Westerners tend to use preferentially high spatial frequency information from foveal vision, whereas Easterners preferentially process contextual information by relying on extra-foveal vision for face recognition (Miellet et al. 2013), change detection of both low-level visual stimuli (e.g., color blocks; Boduroglu et al. 2009), and scene perception (Masuda and Nisbett 2001). The cultural difference in processing styles between Westerners allocating more attention to local and goal-directed objects and Easterners with broader or more holistic processing can emerge as early as 80 ms after the onset of a visual stimulus, suggesting that such cultural difference is deeply ingrained into the early perceptual processing (Kitayama and Murata 2013; Lao et al. 2013).

The different processing styles between Westerners and Easterners also greatly influence how they process facial expressions. For example, Japanese participants are more likely to use overall resemblance rather than local feature matching when they identify a prototypic face for a set of discrete exemplars relative to Caucasian American participants (Miyamoto et al. 2011), and tend to look more at the
surrounding people relative to Westerners (Masuda et al. 2008). Japanese
participants’ rating of emotion of a central person is more influenced by emotions
of other surrounding faces (Ito et al. 2012; Russell et al. 2015), and also shows
greater event-related brain potential (ERP) of N400 (negative-going deflection ERP
around 400 ms after stimulus onset) and the late positive complex (LPC after
500 ms from stimulus onset; Russell et al. 2015). This effect is further shown to be
generalizable even when photos of real faces were used, the saliency of the central
person’s emotion was attenuated, and when viewing time of face images was
limited up to 10 s (Masuda et al. 2012). A recent study demonstrated that Japanese
and Canadian parents’ processing styles play a key role in transmitting such
different processing styles to their children by maintaining their culturally shaped
behaviors in front of their children (Lee et al. 2017). These findings together provide
evidence for cultural variations in affective processing of single faces.

In the current study, we aimed to examine cultural differences in perceiving
crowd emotion from groups of faces varying in emotional expression. We directly
compared crowd emotion perception of Westerners (Caucasian and African-
American participants) versus Easterners (Korean participants) when they were
viewing facial crowds that contained European American faces versus Korean faces.
To our knowledge, this is the first attempt to examine how Westerners and
Easterners perceive crowds of people’s faces from their own cultural or other
cultural groups, broadly construed. Perceiving crowd emotion from groups of
people is an important aspect of social cognition because it allows observers to
evaluate a potential social threat from collective mood of the crowds (Phillips et al.
2014). Facial groups tend to present a greater threat and carry a higher emotional
cost (Douillet et al. 2011) and tend to be perceived as angrier, compared to
individuals (Mihalache et al. 2017). Given the previous findings of different styles
in affective processing (e.g., Ito et al. 2012; Masuda et al. 2008, 2012; Miyamoto
et al. 2011; Russell et al. 2015), we hypothesized that Easterners would more
accurately extract global information from a group of different emotional faces.
Furthermore, emotion expressions on same—versus other race faces are found to be
recognized more accurately (Adams et al. 2009; Elfenbein and Ambady 2002, 2003;
Young and Hugenberg 2010) but require longer processing time (Calder and
2004). The longer processing time is suggested to be the result of more semantic
representations, more resource allocation, and more affective reactions to their
ingroup members (Brewer 1979; Calder et al. 2004; Tajfel and Turner 1986).
Therefore, we also expected to observe greater accuracy and longer response times
for processing their own-race crowds’ emotion versus other-race crowds’ emotion.

Face perception has great social utility because emotional expressions forecast
behavioral intentions of expressers (Adams et al. 2006; Horstmann 2003; Marsh
et al. 2005), which govern observers’ fundamental social motivations accordingly.
From a perceiver’s perspective, for example, an angry face elicits an avoidance
reaction while a happy face elicits approach reaction (Adams et al. 2006; Marsh
et al. 2005; Elliot 1999). The current study sought to examine how human observers
would make use of extracted crowd emotion for these socially relevant and critical
decisions for survival, when they encounter their own race groups’ faces versus
other racial groups’ faces. Rather than just asking which group looks angrier,
therefore, we asked the participants to choose as quickly and accurately as possible which crowd of faces they would rather avoid. Because participants had to choose one of the two facial crowds presented, their decisions required a relative decision between the two. This allowed us to create task settings that were more representative of the type of social appraisal that we are often involved in on a daily basis: e.g., avoiding a group of strangers who look relatively more violent or suspicious in the streets or any other public places. Furthermore, in many cases those expressions may not be extreme but rather subtle. On each trial, we presented two crowds of faces (each crowd comprised either 4 or 6 faces, as in the example shown in Fig. 1c), with one crowd presented in the left, and the other crowd in the right, visual hemifield. Each of the faces in these facial crowds was created by morphing two extreme facial expressions (happy and angry) of the same individual so that they had different emotional intensities ranging from happy to angry. Such manipulation led participants to process and average all the individual members in a crowd to extract the overall emotion of the facial crowd, rather than choosing only one or two individuals.

Experiment 1

Methods

Participants

A total of 25 Korean undergraduate students from Yonsei University (Seoul, South Korea) and 29 U.S. native students from the Pennsylvania State University (State College, PA, USA) participated in Experiment 1. Two participants (one Korean and one American) were excluded from further analyses because they made too many late responses (e.g., RTs longer than 2.5 s); three American participants were excluded because they did not complete the two experimental blocks; one American participant was excluded because of too fast responses (e.g., RTs shorter than 0.2 s) and accuracy lower than chance (50%). Therefore, we ended up with including 48 participants (24 Korean and 24 American). The number of participants included in the current study is sufficient to provide enough statistical power, given our original study on crowd emotion perception where we have shown robust and replicable effects from 20 to 21 participants in each of five successive experiments (Im et al. 2017). Thirteen participants were female among 24 Korean participants (11 male) and 12 participants were female among 24 American participants (12 male). Among the 24 American participants, 19 were European American, two were Hispanic, and three were African American. The average age of Korean participants was 20.29 (SD 1.73) years old and the average age of American participants was 18.75 (SD 1.03) years old. Korean participants were slightly, but significantly older than American participants (mean age difference = 1.54, t(46) = 3.75, p < 0.001). Among 24 Korean participants, three were left-handed and 20 were right-handed (one was unknown), and among 24 American participants, two were left-handed and 22 were right-handed. All the participants had normal color vision and normal or corrected-to-normal visual acuity. The informed written consents were obtained according to the procedures of the Institutional Review Board at Yonsei University and at the Pennsylvania State University for Korean and American participants, respectively. The participants received a course credit for participation in the study.

Apparatus and stimuli

Stimuli were generated with MATLAB and Psychophysics Toolbox (Brainard 1997; Pelli 1997). In each crowd stimulus, either 4 or 6 morphed faces were randomly positioned in each visual field (right and left) on a white background. Therefore, our facial crowd stimuli comprised either 8 or 12 faces. We used face-morphing software (Norrkross MorphX) to create a set of 51 morphed faces from two highly intense, prototypical facial expressions of the same person for a set of six different identities (3 Korean males and 3 European American males, shown in Fig. 1a). The Korean face stimuli were taken from the Yonsei Face Database (Yang et al. 2015), and the White U.S. face stimuli (European American) were taken from the NimStim Emotional Face Stimuli database (Tottenham et al. 2009). The emotional expression
of the faces ranged from 100% happy and 100% angry, with different proportions of
morphing between these two (e.g., the neutral with morph of 50% happy and 50%
angry faces). The morphed face images were linearly interpolated (in 2%
icrements) between two extreme faces. Such a morphing approach was adapted
from the previous studies on ensemble coding of faces (e.g., Haberman and Whitney
2007). One of the two crowds in either left or right visual field was always neutral
(on average), and the other had emotional crowds on average (e.g., very happy
crowd: morphing of angry 32% and happy 68%) somewhat happy; morphing of
angry 40% and happy 60%; somewhat angry: morphing of angry 60% and happy
40%; and very angry: morphing of angry 68% and happy 32%, see Fig. 1b). To
make an emotional crowd have the mean emotion of one of these morphing ratios,
emotionally varying individual faces were randomly chosen from the continuum
between 100% angry and 100% happy.

In order to avoid the possibility that participants simply sampled one or two
single faces from each set and compare them to do the crowd emotion task, we
ensured that 50% of the individual faces in the neutral set were more expressive
than 50% of the individual faces in the emotional sets to be compared. For example,
half of the members of the neutral set were angrier than a half of the members of
the angry crowd. This manipulation allowed us to assess whether participants used such
“sampling strategy” (Myczek and Simons 2008) rather than extracting the average
crowd emotion because sampling one or two members in a set would only yield
50% of accuracy in this setting. On one half of the trials, the emotional stimulus (i.e.,
happy or angry) was presented in the left visual field (LVF) and the neutral
stimulus was presented in the right visual field (RVF), and it was switched for the
other half of the trials. Each face image subtended $2^\circ \times 2^\circ$ of visual angle, and face
images were randomly positioned within an invisible frame subsuming
$13.29^\circ \times 18.29^\circ$, each in the left and right visual fields. The distance between
the proximal edges of the invisible frames in left and right visual fields was $3.70^\circ$. In
order to test the visual hemifield effect, participants were asked to look at the center
fixation before each trial began and keep their eyes fixated to the center during the
stimulus presentation. By using the identical experimental settings including the
size of the display, viewing distance, and the offset between the left and right visual
fields, we have consistently shown the strong and reliable laterality effects on
perception of crowd emotion (Im et al. 2017).

Procedure

Figure 1c illustrates a sample trial. We ensured that both Korean and American
participants performed the tasks in the same experimental settings and procedures.
Participants sat in a chair at individual cubicles and viewed the visual stimuli for 1 s,
which was followed by a blank screen for 1.5 s. The participants were instructed
to make a key press as soon as possible to indicate which of the two facial crowds on
the left or right they would rather avoid. They were explicitly informed that the
correct answer was to choose to avoid the facial crowd showing a more negative (e.
g., angrier) emotion on average. Responses that were made after 2.5 s were
considered late and excluded from data analyses. Feedback for correct, incorrect, or
late responses was provided after each response. The same written instructions were translated into Korean and English to be provided to Korean and American participants to emphasize that it is critical to make responses as quickly and as accurately as they could. The written instructions for Experiment 1 are provided both in English and Korean in Appendix 1.

Korean face stimuli and European American face stimuli were presented in two separate blocks, in a counterbalanced order across participants. Each experimental block had a 4 (different angry/happy morphing ratios: angry 32% + happy 68%, angry 40% + happy 60%, angry 60% + happy 40%, and angry 68% + happy 32%) × 2 (visual field of presentation, LVF and RVF) × 2 (set size: 8 and 12 faces total) design, with 20 repetitions per condition. This yielded 320 trials total, and the sequence of the trials was randomized within each block.

Results

Consistent with our previous studies (e.g., Im et al. 2017; Yang et al. 2013), we did not find any difference in accuracy (all ps > 0.551) and RT (all ps > 0.773) between different set sizes of the facial crowds (8 vs. 12 faces total; Fig. 2a, b) in both cultural groups of participants, suggesting that extraction of crowd emotion does not require serial processing of each individual crowd member, but more likely occurs in parallel. Because there was no effect of crowd size, we collapsed the data from the different crowd size conditions for further analyses.

The overall accuracy for Korean and European American facial crowds was 64.57% (SD 5.13) and 67.17% (SD 5.83) in Korean participants, and 49.26% (SD 6.93) and 59.23% (SD 7.33) in American participants, respectively (Fig. 2c). The accuracy of the Korean participants was higher than the chance level (50%) for both the Korean facial crowds (t(23) = 13.922, p < 0.001) and the European American facial crowds (t(23) = 14.443, p < 0.001). The performance of the American participants was significantly higher than chance only for European American facial crowds (t(23) = 6.170, p < 0.001), but not for Korean facial crowds (t(23) = 0.5245, p = 0.605). Both Korean and American participants showed higher accuracy for European American facial crowds compared to Korean facial crowds, and Korean participants were more accurate than American participants both for Korean and European American facial crowds. Repeated-measures ANOVA with a within-subject factor of the race of facial crowds and a between-subject factor of the culture of participants (Western vs. Eastern) confirmed these observations with the significant main effects of the race of facial crowds (F(1,46) = 27.746, p < 0.001) and the culture of the participants (F(1,46) = 69.34, p < 0.001). The interaction between these factors was also significant (F(1,46) = 9.525, p < 0.01). Specifically, the interaction showed that American participants were less accurate for Korean facial crowds compared to European American facial crowds, whereas Korean participants were equally accurate for both Korean and European American facial crowds. Furthermore, post hoc Tukey’s HSD pairwise comparison tests revealed higher accuracy for European American facial crowds than for Korean facial crowds in American participants (p < 0.05) and higher accuracy in Korean participants.

The error bars indicate the standard error of the mean (SEM). b The set size effect on the overall RT. c Experiment 1: The overall accuracy for Korean and American facial crowds in Korean participants (blue bars) and in American participants (green bars). d Experiment 1: The overall RT for Korean and American facial crowds in Korean participants (blue bars) and in American participants (green bars). e Experiment 2: The overall accuracy for Korean and American facial crowds in Korean participants (blue bars) and in American participants (green bars). f Experiment 2: The overall RT for Korean and American facial crowds in Korean participants (blue bars) and in American participants (green bars).

than American participants, both for Korean and European American facial crowds (p < 0.05).

The median response time (RT) of Korean participants was 1.120 s (SD 0.237) for Korean facial crowds and 1.036 s (SD 0.214) for European American facial crowds. The median RT for American participants was 0.806 s (SD 0.255) for Korean facial crowds and 0.916 s (SD 0.273) for European American facial crowds.
The main effect of the culture of the participants was significant \( F(1,46) = 10.95, p < 0.01 \), with Korean participants being overall slower than American participants. Although the main effect of the race of facial crowds was not significant \( F(1,46) = 0.232, p = 0.632 \), the interaction between the culture of the participants and the race of facial crowds was statistically significant \( F(1,84) = 13.143, p < 0.001 \). Specifically, the interaction showed that Korean participants made faster avoidance responses for European American facial crowds than for Korean facial crowds, whereas American participants made faster avoidance responses for Korean facial crowds than for European American facial crowds. Post hoc Tukey’s HSD pairwise comparison tests confirmed significantly faster RTs for European American than Korean facial crowds in Korean participants \( (p < 0.04) \), and faster RTs for Korean than European American facial crowds in American participants \( (p < 0.05) \). Moreover, RT was significantly faster in American participants than Korean participants for both Korean and European American facial crowds \( (p < 0.05) \).

Our recent work has shown the highly replicable effects of hemispheric asymmetry in reading crowd emotion (Im et al. 2017). As in the current study, participants had to make a relative judgment on which one of the two crowds (either between an angry vs. a neutral crowd or between a neutral vs. a happy crowd) looked angrier and to be avoided. Participants’ accuracy was greater when a facial crowd to be chosen for the avoidance task was presented in the left visual field (LVF) than in the right visual field (RVF), regardless of the actual emotional valence of the facial crowd (whether angry or neutral). Because in the previous study we only recruited American participants and presented them with facial crowds comprising faces from the Ekman face set (Ekman and Friesen 1976), it is not clear whether this right hemispheric advantage for processing the goal-relevant crowd emotion is universal across different cultures. Therefore, we next examined the patterns of laterality effects in Korean and American participants presented with new Korean and European American facial crowd stimuli.

As in the previous study (Im et al. 2017), we found the right hemisphere advantage both for an angry crowd chosen over a neutral crowd and for a neutral crowd chosen over a happy crowd in American participants’ responses to European American facial crowds. As shown in Fig. 3a, the accuracy for an angrier crowd (averaged across the two different morphing ratios: angry 60% + happy 40% and angry 68% + happy 32%) chosen over a neutral crowd (angry 50% + happy 50%) was greater when it was presented in the LVF. Similarly, the accuracy for the neutral crowd chosen over a happier crowd (averaged across the two different morphing ratios: angry 32% + happy 68% and angry 40% + happy 60%) was also greater when it was presented in the LVF. Repeated-measures two-way ANOVA with factors of the visual field containing the facial crowd to be chosen (LVF and RVF) and the emotional valence of the crowd (angrier and neutral) confirmed the significant main effect of the visual field \( F(1,23) = 14.424, p < 0.001 \), specifically, accuracy for the LVF being greater than the RVF. The main effect of emotional valence was also significant \( F(1,23) = 5.749, p < 0.03 \), with the accuracy for the comparison between a neutral versus a happy crowd being greater than the comparison between an angry versus a neutral crowd. The interaction,
Fig. 3 Laterality effect in Experiment 1. a The American participants’ accuracy for American facial crowds when they had to choose an angrier and a neutral facial crowd presented in the LVF and the RVF. The broken line indicates the chance level, 50%. The error bars indicate the standard error of the mean (SEM). b The American participants’ accuracy for Korean facial crowds when they had to choose an angrier and a neutral facial crowd presented in the LVF and the RVF. c The Korean participants’ accuracy for American facial crowds when they had to choose an angrier and a neutral facial crowd presented in the LVF and the RVF. d The Korean participants’ accuracy for Korean facial crowds when they had to choose an angrier and a neutral facial crowd presented in the LVF and the RVF. However, was not significant ($F(1,23) = 0.382, p = 0.543$). Post hoc Tukey’s HSD pairwise comparison tests also revealed significantly higher accuracy for an angry crowd in the LVF than the RVF, and for a neutral crowd in the LVF than the RVF ($p < 0.05$).

Likewise, we also found a significant main effect of the visual field with the Korean facial crowd stimuli ($F(1,23) = 4.919, p < 0.04$; Fig. 3b), with the LVF being more accurate than the RVF. Neither the main effect of emotional valence ($F$
(1,23) = 0.009, p = 0.924) nor the interaction (F(1,23) = 0.006, p = 0.980) was significant for the Korean facial crowd stimuli. Post hoc Tukey’s HSD pairwise comparison tests further revealed significantly greater accuracy both for an angry crowd and for a neutral crowd in the LVF than the RVF (p < 0.05). This is a direct replication of our previous study (Im et al, 2017), in which we showed groups of Ekman faces (Ekman and Friesen 1976) to American undergraduate participants using a different set of white American faces. Furthermore, this result also shows that this laterality effect is still observed in American participants when they view a set of other-race facial stimuli (i.e., Korean faces).

We also examined the laterality effect in the Korean participants’ responses to American and Korean facial crowds separately. For European American facial crowds (Fig. 3c), we observed a similar, but weaker trend in the right hemisphere advantage for the crowd emotion to be chosen: The main effect of visual field was only marginally significant (F(1,23) = 3.045, p = 0.094). The main effect of emotional valence was not significant (F(1,23) = 1.195, p = 0.286), although the interaction was significant (F(1,23) = 4.351, p < 0.05). Post hoc Tukey’s HSD pairwise comparison tests further revealed the nature of the interaction in which a neutral crowd of European American faces was perceived more accurately in the LVF than the RVF (p < 0.05).

For the crowds of Korean faces, we found that the main effect of visual field was not significant (F(1,23) = 0.080, p = 0.780; Fig. 3d). Instead, there was a significant main effect of emotional valence (F(1,23) = 8.684, p < 0.01), with the accuracy being greater when Korean participants had to choose a neutral over a happy crowd than when they had to choose an angry over a neutral crowd. The interaction was also significant (F(1,23) = 6.213, p < 0.03). Post hoc Tukey’s HSD pairwise comparison tests revealed significantly greater accuracy for an angry crowd in the RVF compared to the LVF (p < 0.05), but no significant difference for a neutral crowd in the LVF versus RVF (p = 0.270). Together, American participants seemed to show more pronounced right hemisphere advantage for comparing the emotion of two facial crowds regardless of the race of facial crowds, compared to Korean participants who showed either weak or no right hemisphere advantage.

Previous studies have reported clear sex-related differences in perception of a single face (e.g., Rehnman and Herlitz 2006; McBain et al. 2009; Heisz et al. 2014) and crowds of faces (Bai et al. 2015). As a secondary interest, therefore, we examined whether there were any gender-related differences in accuracy for crowd emotion perception in Korean participants versus in American participants. We conducted a three-way ANOVA with two between-subjects factors of Gender of participants (female vs. male) and Race of participants (Korean vs. American) and a within-subject factor of Race of facial crowds (Korean vs. American). We found the interaction between the two between-subjects factors (Gender of participants x Race of participants) was the only significant effect (F(1,44) = 6.747, p = 0.013). Specifically, Korean male participants were more accurate than Korean female participants both for Korean and European American facial crowds (post hoc t test, Bonferroni-corrected ps < 0.03), whereas there was no significant difference between the accuracy displayed by American male and female participants (post hoc t-test, Bonferroni-corrected ps > 0.111). Lack of accuracy differences between
American male and female participants was also reported in previous work (Im et al. 2017). Other effects (main effect of Gender of participants $F(1,44) = 0.110$, $p = 0.742$), the interaction between the race of the stimulus and the gender of participants ($F(1,44) = 0.095$, $p = 0.760$), the three-way interaction of the race of stimulus, race of participants, and the gender of participants was not significant, either ($F(1,44) = 0.197$, $p = 0.660$).

**Experiment 2**

In the first experiment, we found differences between Korean versus American participants in the overall accuracy, RT, and the laterality effects when they made avoidance decisions about emotional crowds of Korean and European American faces. In particular, we observed substantial differences in the overall accuracy and RT, even though we provided both groups of participants with the same instructions (translated into Korean and English) to emphasize both speed and accuracy of responses. Overall, Korean participants made much slower and more accurate responses, whereas American participants tended to make much faster but less accurate responses. In Experiment 2, we further tested if the differences found were due to a speed-accuracy trade-off between the Korean and American participants. In this follow-up study we employed instructions that differentially stressed speed for Korean participants and accuracy for American participants, respectively. If the difference in perception accuracy between the Korean and American participants was due to a speed-accuracy trade-off in these groups, stressing speed for Korean participants and stressing accuracy for American participants should reduce the group differences. However, if the differences in perception accuracy and speed we observed in Experiment 1 reflect something else (e.g., different perceptual and cognitive styles), rather than a mere speed-accuracy trade-off, we should still observe differences in accuracy and RT between Korean and American participants.

**Methods**

**Participants**

A new group of 46 undergraduate students from Yonsei University ($N = 24$) and from the Pennsylvania State University ($N = 22$) participated in Experiment 2. All the participants had normal color vision and normal or corrected-to-normal visual acuity. One participant was excluded from further analyses because of incomplete experimental blocks. Therefore, we ended up including 45 participants (24 Korean and 21 American). Eleven participants were female among 24 Korean participants (13 male) and 10 participants were female among 21 American participants (11 male; 19 European American and 2 African American). The average age of Korean participants was 20.08 (SD 2.30) years old and the average age of American participants was 18.86 (SD 1.06) years old. Korean participants were slightly, but significantly older than American participants (mean age difference = 1.22, $t$ (43) = 2.23, $p < 0.05$). Among 24 Korean participants, two were left-handed and
20 were right-handed (two were unknown), and 22 American participants, one was left-handed and 21 were right-handed.

**Apparatus and stimuli**

All the aspects of the apparatus and the stimuli were identical to those in Experiment 1.

**Procedure**

All the aspects of the experimental procedure were identical to those in Experiment 1, except that the written and verbal instructions provided to Korean and American participants were revised. For Korean participants, speed was particularly emphasized over accuracy whereas for American participants, accuracy was particularly emphasized over speed. The actual instructions given to Korean and American participants are provided in Appendix 2 both in Korean and English.

**Results**

**Korean participants: stressing response speed**

The median RTs in Experiment 2 were 0.944 s (SD 0.178) for Korean facial crowds and 0.911 s (SD 0.171) for European American facial crowds (Fig. 2f). In order to test whether the different instruction stressing the response speed was effective, we compared the RTs obtained in Experiment 2 with those in Experiment 1. Repeated measures ANOVA with a within-subjects factor of the race of facial crowds (European American faces vs. Korean faces) and a between-subjects factor (Experiment 1 vs. Experiment 2) revealed significantly faster RTs for Experiment 2 than Experiment 1 ($F(1,46) = 7.340$, $p < 0.01$), and significantly faster RTs for European American facial crowds than Korean facial crowds ($F(1,46) = 11.332$, $p < 0.01$), although the interaction was not significant ($F(1,46) = 2.161$, $p = 0.148$). Thus, our new instruction that emphasized the response speed was effective resulting in faster responses of Korean participants in Experiment 2.

Despite the faster RTs for Korean participants in Experiment 2, their accuracy did not decrease significantly (Fig. 2e). Repeated-measures ANOVA showed that Korean participants’ accuracies in Experiments 1 and 2 were not significantly different ($F(1,46) = 0.825$, $p = 0.329$). Therefore, stressing response speed did not seem to impair Korean participants’ response accuracy, but did result in faster RTs. We also found that the accuracy for European American facial crowds was significantly greater than for Korean facial crowds overall ($F(1,46) = 29.258$, $p < 0.001$), replicating the previous study’s results.

**American participants: stressing response accuracy**

In Experiment 1, we observed that American participants yielded much faster, but less accurate, responses compared to Korean participants. Thus, we asked a new
group of American participants to try to spend enough time to view the stimuli and respond as accurately as possible in Experiment 2. However, the new instructions emphasizing accuracy over speed did not seem to improve American participants' accuracy. The accuracy was 52.71% (SD 6.777) for Korean facial crowds and 53.44% (SD 7.319) for European American facial crowds (shown in Fig. 2e). Repeated-measures ANOVA revealed that the accuracy in Experiment 2 was not significantly different from that in Experiment 1 ($F(1,43) = 1.917, p = 0.173$), although the main effect of the race of facial crowds ($F(1,43) = 14.02, p < 0.001$) and the interaction ($F(1,43) = 10.46, p < 0.01$) were significant. We found a similar pattern for RTs of American participants in Experiment 1 versus Experiment 2: The RTs for Experiment 1 were not significantly different from those for Experiment 2 ($F(1,43) = 1.285, p = 0.263$); and the RTs for Korean facial crowds were faster than for European American facial crowds ($F(1,43) = 4.318, p < 0.05$; Fig. 2f). Thus, we conclude that the instructions to American participants to focus on accuracy instead of speed failed to shift the participants' speed-accuracy trade-off criterion and did not significantly influence American participants' accuracy or RT. Comparing the accuracy and RT of Korean versus American participants, post hoc Tukey's HSD pairwise comparison tests showed greater accuracy for the Korean participants than for the American participants both for Korean and European American facial crowds ($p < 0.03$), but no difference in RT between Korean and American participants for Korean or European American facial crowds ($p > 0.11$). We also found that the RT of Korean participants was faster for European American facial crowds than Korean facial crowds, whereas the RT of American participants was faster for Korean facial crowds than European American facial crowds (all $p < 0.05$), replicating the results of Experiment 1.

Finally, we tested the laterality effects in making avoidance decision between two facial crowds when different instructions stressing either speed or accuracy were given to participants. As shown in Fig. 4a and b, we found the same laterality effect when American participants viewed European American facial crowds and Korean facial crowds that we observed in Experiment 1. Both for American and Korean facial crowds, American participants in Experiment 2 were more accurate both for an angry crowd and a neutral crowd when they were presented in the LVF than the RVF. This was confirmed by a repeated-measures ANOVA with significant main effect of visual field (European American faces: $F(1, 20) = 4.692, p < 0.05$; Korean faces: $F(1, 20) = 4.370, p < 0.05$), and by significant Post hoc Tukey's HSD pairwise comparisons for an angry crowd in the LVF versus RVF, and for a neutral crowd in the LVF versus RVF ($p < 0.05$). Unlike American participants, Korean participants showed weaker effects of the right hemisphere advantage. For European American facial crowds, the main effect of visual field was marginally significant ($F(1,23) = 3.250, p = 0.08$; Fig. 4c), with Korean participants' accuracy being greater for an angry crowd and a neutral crowd presented in the LVF than the RVF. Tukey's HSD pairwise comparisons showed that the accuracy was significantly greater for an angry crowd and a neutral crowd in the LVF than the RVF ($p < 0.05$). For Korean facial crowds, Korean participants did not show a significant main effect of visual field ($F(1,23) = 0.008, p = 0.931$; Fig. 4d), although the main effect of emotional valence was marginally significant ($F(1,23) = 3.094, p = 0.092$), with the accuracy
Fig. 4 Laterality effect in Experiment 2. a The American participants’ accuracy for American facial crowds when they had to choose an angry and a neutral facial crowd presented in the LVF and the RVF. The broken line indicates the chance level, 50%. The error bars indicate the standard error of the mean (SEM). b The American participants’ accuracy for Korean facial crowds when they had to choose an angry and a neutral facial crowd presented in the LVF and the RVF. c The Korean participants’ accuracy for American facial crowds when they had to choose an angry and a neutral facial crowd presented in the LVF and the RVF. d The Korean participants’ accuracy for Korean facial crowds when they had to choose an angry and a neutral facial crowd presented in the LVF and the RVF.

being greater when Korean participants chose a neutral over a happy crowd than when they chose an angry over a neutral crowd.

Finally, we examined the gender differences in Korean versus American participants. We conducted a three-way ANOVA with two between-subjects factors of Gender of participants and Race of participants and a within-subject factor of the Race of facial crowds. Only the three-way interaction of Race of the facial crowd, Race of participants, and Gender of participants was significant ($F(1,41) = 6.887$, $p < 0.05$).
Specifically, we observed that American female participants had higher accuracy for Korean facial crowds than American male participants (post hoc t-test, Bonferroni-corrected $p = 0.051$). However, there was no difference in accuracy for European American facial crowds between American female versus male participants (post hoc t-test, Bonferroni-corrected $p = 0.229$), again replicating our previous finding (Im et al. 2017) from American female versus male participants when they viewed only European American facial crowd stimuli. For Korean participants, no gender-related differences reached significance. There was no main effect of Gender of participants ($F(1,41) = 0.145, p = 0.706$), no interaction between Gender of participants and Race of stimulus ($F(1,41) = 2.422, p = 0.127$), nor an interaction between Gender of participants and Race of participants ($F(1,41) = 0.351, p = 0.557$).

**General discussion**

The current study examined cultural differences between American and Korean participants in processing crowd emotion of faces belonging to either their own or another racial group. Here we report three main findings: (1) Korean participants were more accurate overall relative to American participants in choosing the angrier facial crowd to avoid, for both Korean and European American faces; (2) Korean participants made faster avoidance responses for European American facial crowds than for Korean facial crowds, whereas American participants made faster responses to Korean facial crowds than to European American facial crowds; (3) American participants showed highly lateralized response patterns in which they were significantly more accurate in choosing a facial crowd to avoid when it was presented in the left visual hemifield than in the right visual hemifield, indicating a right hemisphere advantage for processing crowd emotion. However, Korean participants showed weak to nonexistent laterality effects, with a slight right hemisphere advantage for European American facial crowds, and no right hemisphere advantage in perceiving Korean facial crowds.

The overall superior accuracy Korean participants displayed was not simply due to a speed-accuracy trade-off. Although Korean participants were much slower than American participants in Experiment 1, the instructions to Korean participants to focus on speed in Experiment 2 lowered their RTs to be on par with those of American participants, while their higher level of accuracy compared to American participants was maintained despite speedier responses. Conversely, American participants were less accurate than Korean participants in both Experiment 1 and 2, even when they were explicitly instructed to focus on making correct responses. One possibility is that the better accuracy in Korean participants compared to American participants for perceiving crowd emotion may be attributable to the higher sensitivity of global information extracted through holistic processing by Easterners compared to Westerners (Abel and Hsu 1949; Ji et al. 2000; Kitayama et al. 2003; Masuda and Nisbett 2001; Nisbett 2003; Nisbett and Miyamoto 2005; Norenzayan and Nisbett 2000; Peng and Nisbett 1999). Such tendency can generalize to social contexts, suggesting that Westerners tend to see emotions in a
group as a collection of individuals' feelings, whereas Easterners tend to see them as a group feeling. For example, Masuda et al. (2008) presented a set of cartoon pictures of an individual surrounded by a group of four other people and asked Japanese and Western participants to judge the emotion of the central person. They found that the emotion expressed by people surrounding the central person in the stimulus influenced judgment on the emotion of the central person in Japanese, but not in Western participants, and that Japanese participants looked at the people surrounding the central person more than Westerners did. Moreover, our finding is also in line with the previous studies that showed American participants perform better in the absolute task (e.g., reporting absolute length of a vertical line) whereas Japanese perform better in the relative task (e.g., reporting relative length proportion to the height of the surrounding frame around a vertical line; Hedden et al. 2008; Kitayama et al. 2003) and that Chinese participants are better at detecting co-occurrence and co-variation of events compared to American participants (Li et al. 2000). Consistent with these previous findings, Korean participants in the current study showed a behavioral advantage on the global task in general, compared to American participants. However, the holistic processing pattern in Easterners can also be disruptive in some other cases when they have to process local features that are surrounded by interfering context or background (e.g., Masuda et al. 2008).

We found that both American and Korean participants made faster avoidance responses when they viewed facial crowds of other races (e.g., American participants being faster for Korean facial crowds and Korean participants being faster for European American facial crowds). Such a speed advantage for other-race faces has been previously observed in single face classification and recognition of human subjects (Caldara et al. 2004) and similar attentional bias toward conspecifics' emotions in primates (Kret et al. 2016). For example, by presenting Caucasian participants with single faces of Caucasians versus East Asians, Caldara et al. (2004) found that other-race faces (e.g., Asian faces) are classified faster than same-race faces (e.g., Caucasian faces). They suggested that typically lesser experience with other-race faces engenders fewer semantic representations, which in turn increases the speed of processing for such stimuli. Moreover, it has been suggested that people tend to be more favorable, in terms of affective reactions and resource allocation, to members of their own group (in-group) than to other groups (Brewer 1979; Tajfel and Turner 1986). Allocating fewer resources to detailed features in out-group faces would also lead to insufficient individuation of members of the group, as it is known as the “out-group homogeneity effect” (Linville et al. 1986; Messick and Mackie 1989; Mullen and Hu 1989; Park et al. 1991; Quattrone 1986; Wilder 1986). These factors could have contributed to our new findings of faster avoidance responses to facial crowds of other-race faces in both American and Korean participants. Therefore, our findings provide a conceptual replication and expansion of theories of group perception, specifically defined by race, in more naturalistic social settings where observers perceive groups of emotional faces and make an affective evaluation between the groups.

Hemispheric asymmetry allows for processing of incoming perceptual inputs in parallel for competing goals (Rogers et al. 2013). Goal-dependent parallel processing is particularly useful when a large number of complex stimuli (such
as a crowd of emotional faces) and competing cognitive goals tax the processing
capacity of the visual system, as was the case in our task. For example, the right
hemisphere (RH) is suggested to dominate in attending to novelty, detecting
behaviorally goal-relevant, clear sensory events, executing rapid responses, and
extracting global features, whereas the left hemisphere (LH) is thought to control
responses for consideration of alternatives, to resolve ambiguities, and process local
features by inhibiting LH (Corbetta and Shulman 2002; Rogers and Andrew 2002;
Robertson et al. 1988). Recently, we have shown that the pattern of hemispheric
lateralization in reading crowd emotion is dependent on the ongoing task goal in the
context of social decisions (Im et al. 2017). The right hemisphere advantage that
was observed in Im et al. (2017) such that the facial crowd to be chosen (e.g., an
angry crowd to be chosen over a neutral crowd and a neutral crowd to be chosen
over a happy crowd during the avoidance) was perceived more accurately in the
LVF than the RVF. Such an RH advantage is consistent with previous studies that
have shown that the RH is dominant for global processing whereas the LH is
dominant for local processing (e.g., Christie et al. 2012; Delis et al. 1986; Robertson
et al. 1988; Roberson and Ivry 2000; Yovel et al. 2001). Because Im et al. (2017)
presented American participants only with Caucasian faces selected from the
Ekman face set (Ekman and Friesen 1976), it was unclear if this effect could be
generalized to other cultural groups. The current study not only replicates their
findings by using different stimuli (both for Caucasian and Korean facial crowds) in
a different cohort of American participants, but also shows that Korean participants
exhibit much weaker or minimal effects of the right hemisphere advantage
compared to American participants. Instead of the right hemisphere advantage,
Korean participants showed what may appear to be a positive emotion bias, with
better accuracy for the comparison of a neutral versus a happy crowd, but only for
own-race faces (Korean facial crowds). Although this is a novel and interesting
finding, it needs to be interpreted with caution. Because they performed a relative
comparison task between two crowds (e.g., one neutral and the other happier), this
effect could be the result of either a negative bias, if Korean participants were more
likely to perceive a neutral crowd of Korean faces as being angrier, or a positive
bias, if they were more likely to perceive a happy crowd of Korean faces as being
happier. Future research efforts will be necessary to clarify this effect.

The current findings on differences in hemispheric lateralization between
American participants (e.g., highly lateralized) and Korean participants (e.g.,
weakly or not lateralized) may reflect the different breadth of attention that results in
different styles of engaging in the task and achieving the task goals. Where previous
research has found that similar neural responses were recruited when processing
same-culture facial stimuli (i.e., Japanese versus European Americans: Adams et al.
2010), the differences in laterality effects found here suggest distinct neural
responses being recruited in participants from these cultures. This could be due to
Eastern/Western differences in perceptual attention (see Park and Kitayama 2010).
Westerners are suggested to be more narrowly focused, whereas Easterners have
been suggested to have a broader focus, or be more holistic in the application of
attention to perceptual objects (Nisbett et al. 2001). Kitayama and Murata (2013)
suggested that focused attention, more dominant in Westerners than Easterners,
might be due to their strong independent orientation and corresponding tendency to pursue an action towards a goal-relevant object from the very beginning of processing (Kitayama and Murata 2013; Markus and Kitayama 1991; Varnaum et al. 2010a, b). Conversely, global attention for holistic processing, dominant in Easterners, might be due to their tendency to be receptive to a wider range of incoming information, which in turn allow them to adjust their behaviors accordingly (Kitayama and Murata 2013). Along with such qualitative differences in attentional breadth that results in different cognitive styles and strategies between Westerners and Easterners, the current study provides novel empirical evidence for cross-cultural variation in hemispheric lateralization closely associated with socio-affective decision-making in different cultural groups.

Previous studies have also reported qualitatively different patterns of hemispheric lateralization between Westerners and Easterners. To illustrate, Western subjects were better with stimuli presented in the left visual hemifield while Japanese subjects showed visual field symmetry in response to geometric shapes (Hatta and Dimond 1980); Westerners showed bilateral activity to face stimuli in the fusiform face area (FFA) whereas Easterners showed more right lateralization (Goh et al. 2010); and Westerners showed left hemisphere (LH) dominance whereas Easterners showed right hemisphere (RH) dominance in the baseline activation (Moss et al. 1985) during the EEG resting state (with eyes-closed). Although the results are mixed, allowing for only limited conclusions, these findings along with our own findings suggest that there may be cross-cultural differences in hemispheric lateralization that reflect ethnic characteristics in behaviors, such as biases in perception, attention, cognition, and social attribution.

**Limitations and future research**

Before concluding, it is worth noting that our findings may be interpreted with respect to other hypotheses. Although our findings are consistent with the well-accepted framework on two distinct cognitive styles of information processing in Western and Eastern observers (analytical vs. holistic, respectively), several alternative explanations for our findings are also possible, due to a variety of practical constraints and confounding factors associated with cross-cultural experimental research. We wish to acknowledge three major alternative possibilities in interpreting our results.

First, it may be the case that Korean and American participants have used different implicit rules and criteria regarding the balance between speed and accuracy. Although we manipulated the test instructions and showed that the differences in accuracy and RT between Korean and American participants did not merely reflect differences in the speed-accuracy trade-off, we cannot completely rule out different tendencies in Korean and American participants to emphasize speed or accuracy, regardless of the instruction. American norms for timed measures typically remain within normal limits for a single error, suggesting a relatively specific speed-accuracy trade-off valued in American culture (Strutt et al. 2015). However, in other cultures speed and quality can be considered
contradictory, and these cultures highlight the relative importance of accuracy over speed, for a good product is the result of a slow and careful process (Ardila 2007). Our results may partly support this possibility in that Korean participants did not sacrifice their accuracy for speed when they were instructed to focus on making fast responses, while American participants did not slow down their responses when they were instructed to spend more time to be more accurate. Future work should specifically address such cross-cultural differences in speed-accuracy trade-off criteria to better understand how their influence on various perceptual and cognitive tasks.

Second, it is possible that the better overall accuracy in Korean participants than in American participants results from the type of the task we employed: avoiding one of the two emotional facial crowds. It has been shown that North Americans tend to be more attentive to approach-oriented information, whereas East Asians tend to be more attentive to avoidance-oriented information. For example, Hamamura et al. (2009) showed that American participants recalled more items describing approach-motivating events (e.g., gorgeous weather for hiking) whereas Japanese recalled more items describing avoidance-motivating events (e.g., stuck in a traffic jam). Moreover, it has been shown that Korean participants were more likely to embrace avoidance personal goals relative to European Americans (Elliot et al. 2001); Americans rated a tennis game that was framed as an opportunity to win as more important than one that was framed as an opportunity to avoid a loss, whereas Chinese participants showed the reverse pattern (Lee et al. 2000); and Canadian participants were motivated by success feedback more than failure feedback whereas Japanese participants were motivated by failure feedback than success feedback (Heine et al. 2001; Oishi and Diener 2003). Likewise, the better accuracy for Korean participants than Americans in the current study may be also associated with the avoidance task that we employed.

Finally, given that the face stimuli were morphed between extreme happy and extreme angry, it is possible that Korean participants are better at processing mixed emotions. It has been suggested that Easterners value and report experiencing more mixed emotion, for example, feeling happy and sad at the same time, compared to Westerners (Miyamoto et al. 2017). Thus, it is possible that Korean participants could have been more accurate for processing each of the morphed faces in our facial crowds as well because of their better ability to read mixed emotion (e.g., subtle variation of emotions) from each morphed face as a result of mixture of happy and angry expressions. This is an interesting possibility that should be further investigated by future studies by comparing the ability of Easterners and Westerners to properly read complicated and mixed emotions from facial expressions. Moreover, it has been shown that Easterners rely on the eye region more, and on the mouth region less, than Westerners when they process facial expressions (Yuki et al. 2007). Thus, characterizing different patterns of eye movements across cultural groups during perception of crowd emotion of own-race versus other race faces will be informative in understanding how Easterners and Westerners extract important social information to judge crowd emotion. In the current study, we were
primarily interested in the comparison between different cultural groups (Korean vs. American) of participants to examine how sociocultural factors shape people’s group perception. However, another potentially interesting avenue of research is exploring how participants’ ethnicity interacts with cognitive aging and gender-related differences in perception of crowd emotion. Future cross-cultural studies of aging and gender effects will further investigate this with larger and more balanced sample size between age and gender groups.

Conclusion

In conclusion, the current study reports cross-cultural differences between American and Korean participants in reading crowd emotion in groups of faces. Cultural differences in group perception are a rarely investigated topic, although it seems that differences in social norms between different cultural and ethnic groups may be closely related to their interpersonal perception and interactions. Our work offers an initial inquiry into cross-cultural differences in ensemble perception of faces with great social significance by presenting the same visual stimuli to two different cultural groups. Our work is an initial step to bridge a gap between the literature on ensemble coding of facial stimuli and a burgeoning area of cross-cultural work showing the importance of culture in understanding social perceptual processes.

Appendix 1: Instruction for Experiment 1

a. Instruction written in Korean (for Korean participants)

"매 시험마다 두 그룹 (왼쪽, 오른쪽)의 얼굴들이 제시됩니다. 모든 얼굴들은 서로 다른 표정을 가지고 있습니다. 두 그룹의 얼굴들 중에서 어느 그룹의 얼굴을 피하고 싶은지 선택하는 과제입니다. 왼쪽 그룹을 피하려면 'F' 키를, 오른쪽 그룹을 피하려면 'J' 키를 눌러주세요. 매 시험 후 피드백이 주어집니다. 정답은 전체적으로 더 부정적인 그룹을 선택하는 것입니다. 최대한 빨리, 그리
b. Instruction written in English (for American participants)

“In this experiment, you will be presented with two crowds of faces with varying emotional expressions. Your task is to choose which of the two groups of people (on the left or right) you would rather avoid. Press ‘F’ for left group, and press ‘J’ for right group on the display. The stimulus image will be presented very briefly. Please try to make a response as soon as possible. Also, please try to remain as accurate as possible. If you are ready to start, press a space key.”

Appendix 2: Instruction for Experiment 2

a. Instruction for Korean participants

[Korean version as in the actual experimental session] “매 시행마다 두 그룹 (왼쪽, 오른쪽)의 얼굴들이 제시됩니다. 모든 얼굴들은 서로 다른 표정을 가지고 있습니다. 두 그룹의 얼굴들 중에서 어느 그룹의 얼굴을 피하고 싶은지 선택하는 과제입니다. 왼쪽 그룹을 피하려면 F 키를, 오른쪽 그룹을 피하려면 J 키를 눌러 주세요. 매 시행 후 피드백이 주어집니다. 정답은 전체적으로 더 부정적인 그룹을 선택하는 것입니다. 최대한 빨리 그리고 정확하게 반응해 주시기 바랍니다. 특히, 빠르게 반응하는 것이 중요합니다. 자극에 대한 첫인상을 바탕으로 응답해 주세요. 빠르게 응답한 시험만이 실험 결과 분석에 사용될 예정이며, 너무 느리게 응답한 시험은 분석에서 제외됩니다. 자극은 1조간만 보여집니다. 시작하려면 space key를 눌러주세요.”

[English version, translated from Korean] “On each trial, two crowds of faces with varying emotional expressions will be presented for 1 s. Your task is to choose which of the two groups of people (on the left or right) you would rather avoid. Press ‘F’ to avoid left group, and press ‘J’ to avoid right group on the screen. Correct answer is to choose angrier (more negative) crowd on average. Feedback will be provided on each trial. Please try to remain as accurate as possible. However, we require fast responses for our analyses. Accuracy at the expense of speed will undermine our study, because responses that are too slow cannot be analyzed. Please rely on your first impression of the stimuli and try to make response as quickly as you can.”

b. Instruction for American participants

On each trial, two crowds of faces with varying emotional expressions will be presented for 1 s. Your task is to choose which of the two groups of people (on the left or right) you would rather avoid. Press ‘F’ to avoid left group, and press ‘J’ to avoid right group on the screen. Correct answer is to choose angrier (more negative) crowd on average. Feedback will be provided on each trial. Please try to remain as fast as possible. However, we require accurate responses for our analyses: Speed at
the expense of accuracy will undermine our study, because only accurate responses can be analyzed. Please try to make response as accurately as you can.
